

N.Z.M.O. CIRCULAR NOTE No. 43.

MEAN VALUES OF HEIGHTS OF TROPOPAUSE, 300, 500, and 700
MILLIBAR SURFACES AT AUCKLAND, HOKITIKA AND TAIERI.
By I.S. KERR.

Monthly means of the height of the tropopause and of the 300, 500 and 700 millibar surfaces have been computed from the radiosonde data available from Auckland, Hokitika and Taieri.

Radiosonde observations have been made at Auckland almost continuously, one flight a day at 1200 Hours G.M.T. from May, 1943 to date; at Hokitika; from October, 1944 to November, 1945, inclusive, one flight a day at 1200 hours G.M.T., and occasional flights from August, 1946 to date; at Taieri; from February, 1944 to November, 1945, inclusive, one flight a day at 1200 hours G.M.T., and a few training flights since.

The periods used for the computation of the mean values presented in this note were:

Auckland : - May, 1943 to April, 1947.

Hokitika : - October, 1944 to November, 1945

Taieri : - February, 1944 to November, 1945.

The height of the tropopause, H_t , was determined according to the following rules:

- (a) When the stratosphere begins with an inversion, H_t is the height of the first point of zero temperature gradient.
- (b) When the stratosphere begins with an abrupt transition to a temperature gradient below 2°C per kilometre without inversion H_t is the height of the abrupt transition.
- (c) Where there is no such abrupt change of temperature gradient, the base of the stratosphere is to be taken at the point where the mean fall of temperature for the next kilometre above is 2°C or less, provided that it does not exceed 2° for any subsequent kilometre.

The means are presented in two equivalent sets of tables, the first set giving values in geodynamic metres, the second set in conventional feet (i.e. the unit is 0.98 of one geodynamic foot) and a set of curves showing the annual variation and comparisons between Auckland, Hokitika and Taieri. The curves are smoothed i.e. the values entered on the graphs are obtained from the formula $b' = \frac{1}{3}(a + 2b + c)$, where b is the actual mean for a given month, a and c the actual means for the months preceding and following the given month and b' the smoothed mean for the given month.

The chief purpose of this note is simply to present the mean values but a few observations may be made.

Height of the Tropopause. The means of all observations for each station, 11.0 gkms. for Auckland, 10.4 for Hokitika and 10.3 gkms. for Taieri accord fairly well with, but appear to be slightly lower than, figures quoted for corresponding latitudes in the northern hemisphere. (1). Bureau, Douguet and Wehrle (2), in 1939, obtained a series of atmospheric soundings from Madagascar to Kerguelen and back. In their report they say that all soundings at Kerguelen showed "the base of the stratosphere at once.....much lower and much warmer than.....at Paris" in about the same latitude. It will be interesting to see if Australian soundings also show tropopauses lower than in the northern hemisphere at corresponding latitudes. The downward slope of the mean tropopause towards the pole is illustrated. The amplitude of the annual variation at Auckland, 3 gkms, is in close agreement with Gold's figure for Europe (1910-11) (1), 2.5 gkms.

The fact that the amplitude at higher latitudes (Hokitika and Taieri) is smaller than at Auckland is in agreement with Northern Hemisphere observations and the magnitude of the difference appears to correspond roughly with the difference between the amplitudes at 40° N and 50° N (see diagram due to Ramanathan on P.18 of Brunt's "Physical and Dynamical Meteorology"). Mean values at Taieri and Hokitika higher than at Auckland in July and August are surprising but may be due to abnormalities during these months of the years 1944 and 1945 for which Taieri and Hokitika (1945 only) data are available. The means for the individual months are shown in Table.

	July 1944	August, 1944	July, 1945	August, 1945
Auckland	10.0	9.4	9.7	10.2
Hokitika	-	-	10.1	10.2
Taieri	10.3	10.4	10.3	10.4

There are however two facts which point to the possibility that this reversal of the slope of the tropopause in winter is genuine. The first is that the reversal is complete i.e. Taieri tropopause is higher than Hokitikas which in turn is higher than Auckland. The other is that it has been shown (N.Z.M.O. Circular Note No.25) that the passage of depressions over the North Island is common and most frequent in winter. This is also interesting in view of the Little America III observations (3) which indicate a disappearance of the tropopause over the Antarctic in Winter and temperature at high levels much colder in Winter than in Summer.

The December means for Hokitika and Taieri are based on only one month's observations in 1944 when the Auckland mean was 10.7 gkms, which is 0.7 gkms. lower than the Auckland December mean for four years.

Heights of 300, 500 and 700 Millibar Surfaces. The main features of the curves of Figures 1 b to 1 d are much the same as those of Figure 1a but of course the amplitude of the annual variation decreases with increasing pressure. The heights of the surfaces lower polewards and in all months the Auckland mean heights are higher than Hokitika's and Taieri's. All surfaces are at a maximum height at all stations in February (smoothed values). Over Taieri however there are signs of a double minimum in the 300 millibar curve in June and September. This is more marked at the 500 millibar level and at this level Hokitika exhibits the same tendency. At the 700 millibar level the minima at Hokitika and Taieri occur in May and November. (Note: the smoothing process results in the exceptionally low December, 1944 values of the 700 mb. height for Hokitika and Taieri being reflected in the November values; the true minima would appear from the tables of unsmoothed values to be in October). The Auckland smoothed curve of 700 millibar heights exhibits no double minimum but there is a distinct flattening of the curve between May and September. The un-smoothed Auckland 700 mb values in Table I show two minima, in May and August. The period during which radiosonde observations have been taken at Hokitika and Taieri is however too short to show conclusively whether or not the double minimum is real.
